**Abstract:** We present a new record of the Crested Eagle, *Morphnus guianensis* (Daudin, 1800), a rare forest eagle of the Neotropics on 22 May 2012 at a Cerrado area in Minas Gerais state, southeastern Brazil. The species has only two historical records in the state, both at areas formerly covered by Atlantic Forest. The finding raises the expectations for the maintenance of the species in the state, stressing the fact that this is the first species record in a Cerrado area in Eastern Brazilian states.

**Key words:** Crested Eagle, arpía menor, uiraçu-falso, raptors, geographical range, Neotropical savanna

The Crested Eagle, *Morphnus guianensis* (Daudin, 1800), is one of the rarest Accipitriformes in the Neotropics. Adults resemble the juvenile of the Harpy Eagle, *Harpia harpyja* (Linnaeus, 1758), but are lighter, smaller, and have a single crest, not divided into two horns as in the latter (Thiollay 1994). There are dark phase individuals, similar to the adults of the Black Hawk-Eagle, *Spizaetus tyrannus* (Wied, 1820) (Sick 1997) and intermediate plumage patterns are also known (Hilty and Brown 1986).

Its range spreads across the Neotropics from Guatemala and Honduras in Central America, west-central Colombia west of the Andes. In the east of Andes in South America the species is found at countries up to Paraguay and northeastern Argentina (Misiones) (Thiollay 1994; Sick 1997; Ferguson-Lees and Christie 2001). Inhabits humid lowland and subtropical forests and, in its southern range, it is known to occur in gallery forests (Hilty and Brown 1986; Thiollay 1994, Ferguson-Lees and Christie 2001). In Brazil the species has been known from a couple of sites formerly covered by evergreen or semideciduous forests in the Amazon and the Atlantic forest realms (Sick 1997) with one historical record (1899) in the extreme northwest of the state of Rio Grande do Sul (Belton 2000). All the recent 19 photographic records in the internet for Brazil were obtained in the Amazonian part of the country (Wikiaves 2013).

There are only two records of *M. guianensis* for the state of Minas Gerais, both in Atlantic Forest areas. The first record is given by Mattos et al. (1993) a bird seen at the Serra das Quatro Patacas currently encompassed by the Mata Escura Biological Reserve, in Jequitinhonha county (16°23′ S, 041°02′ W) during the 1970s (G. T. Mattos pers. comm.). The second record was done at Caparaó National Park, at Alto Caparaó county (20°24′23″ S, 041°50′13″ W) (Zorzin et al. 2006).

Like other raptors, *M. guianensis* face conservation threats mainly due to habitat loss and hunting (Thiollay 1984; BirdLife International 2013) and their world conservation status is Near Threatened (IUCN 2013). Outside the Amazon the species has been vanished, being classified as critically endangered in Minas Gerais (Fundação Biodiversitas 2007; COPAM 2010), Espírito Santo (Simon et al. 2007), São Paulo (SÃO PAULO 2008) and Santa Catarina (CONSEMA 2011), probably extinct in Rio de Janeiro (Alves et al. 2000), extinct in the wild in Rio Grande do Sul (Fontana and Bencke 2003) and probably extinct in Paraná (Mikich and Bernils 2004). Although eastern Brazilian populations have been shrinking along the decades, the wide distribution of the Crested Eagle in the Amazon has prevented it to be classified as an officially threatened species at the national level (Silveira and Straube 2008).

We report what seems to be the first known record of *M. guianensis* in a Cerrado area in eastern Brazil. (Thiollay 1994; Silva 1995; Pinheiro and Dornas 2009; Faria et al. 2009; Tubelis 2009) The observation took place in a ecotone between Cerrado sensu stricto and gallery forest at the Reserva do Meleiro, a 1,366 ha...
Although it is common knowledge among the ornithological community that *M. guianensis* needs vast tracts of primary forest to live (Withcare 2012; Ferguson-Lees and Christie 2001; Jullien and Thiollay 1996) our record could suggest that the species could be adapting to fragmented areas or open areas as observed by Crease and Tepedino (2013) in Venezuela. However, our sole record does not support such hypothesis, which is also weakened by the extinction of the species in other fragmented areas (Jullien and Thiollay 1996). Oliveira and Silva (2006) attributed a similar record for *H. harpyja* in a Cerrado region, to its migratory behavior or dispersal. As there is no report of migration nor of persistent use of fragmented areas by *M. guianensis*, adult vagrancy or postnatal dispersal is the best explanation for the records we have done. Albuquerque et al. (2006) report on two sightings of *M. guianensis* in ecotonal areas between evergreen forests and natural grasslands of Santa Catarina state, but they also discard the possibility of adaptation to anthropized areas. There is no larger area of contiguous Cerrado larger than the Reserva do Meleiro in a radius of about 35 km and more extensive preserved areas such as the neighbor Serra do Cabral and part of the Espinhaço Range, are dominated by campos rupestres. However, these mountain ranges have forests in deep ravines which may work as refuges for large raptors (Canuto et al. 2012). Thus, the possibility that the individuals seen are effectively living in the region, using the Reserva do Meleiro as an important part of a multi-habitat territory must be investigated.

Ideally, satellite tracking should be used to shed light on this issue.

The syntopy of M. guianensis, S. ornatus and U. coronata has been already reported in southern Brazil (Albuquerque et al. 2006). Although our records are not concurrent, they indicate that the same could happen at Felixlândia region. The Reserva do Meleiro and the other few areas of protected Cerrado of similar size were created by the forestry companies established in the region since the 1970s and are maintained by them. Their creations were demanded as environmental compensation actions for the conversion of large areas of Cerrado into eucalyptus monocultures. As the farmer nearby do not maintain any areas of native Cerrado of similar size, even isolated or in blocks, that could maintain species demanding large forested areas, such as the threatened raptors reported here. Although the Reserva do Meleiro is large for the local standards it is tiny to conserve, by itself, a population of large raptors. However, it exemplifies the fact that the creation and maintenance of large and contiguous reserves by companies, notwithstanding the vast areas they converted into eucalyptus monoculture, must be stressed as an important contribution to bird conservation. In fact, given the highly degree of devastation of the Brazilian Cerrado by the agribusiness and the projections for the inefficiency of the currently set of reserves to conserve Cerrado birds under climate change in the decades to come (Marini et al. 2009) these reserves will be even more important to bird conservation in general. However, its effectiveness for the conservation of raptors, especially those focused in this article should be evaluated by long-term monitoring.

ACKNOWLEDGEMENTS

We thank Planep-Plantar Empreendimentos S. A. for supporting the bird monitoring activities that allowed us to record the raptors. Izaias de Jesus Rodrigues and Thiago Morais helped with logistical support. João Victor A. Lacerda and Henrique Caldeira Costa for reviewing the manuscript. Gabriel Mello for editing the photographs. Giancarlo Zorzini for the suggestions.
